A Navigation Solution Involving Changes to Course and Speed

George H. Kaplan
U.S. Naval Observatory

Abstract In a previous paper [1], an approach to celestial navigation was presented that allows a vessel’s latitude, longitude, course, and speed to be simultaneously estimated. The development assumed that the vessel was sailing a rhumb-line track at a constant speed. In this paper, the approach is extended to cover the case where observations are taken over several legs of a voyage. A single least-squares solution for all sailing parameters is developed. The algorithm presented in this paper is not limited to celestial navigation, but is applicable to any situation in which observations over several legs of a voyage are to be combined in a single solution.

Key Words celestial navigation, celestial fix, motion of observer

Introduction

A development of celestial navigation was presented in [1] in which the motion of the observer was included as an essential part of the basic mathematics. This allows celestial observations to be used for the determination of not just latitude and longitude at a specific instant (the traditional fix), but also course and speed—providing, of course, that a sufficient number of observations are available, suitably distributed in azimuth and time. The development in [1] assumes that the observer’s vessel is sailing a rhumb-line track at constant speed during the observations. For altitude sights made with a hand-held sextant (typical accuracy \( \pm 1 \) arcmin), at least eight observations, spread over several hours, are generally needed for reliable course and speed estimates. However, the time span over which the observations need to be made would be less if their accuracy were better. For example, an automated shipboard star tracker might make the necessary observations and obtain a good solution in a matter of minutes.

The algorithm described in [1] has been implemented in software specifically designed for U.S. Navy operational use. Navy ships are subject to changes in orders en route, and are often involved in maneuvers. The software was therefore required to handle an arbitrary number of changes to course and speed. Even on an uncomplicated port-to-port voyage, the great-circle route would usually be approximated by a series of rhumb lines. The possibility that a celestial fix might involve observations that span two or more voyage legs had to be considered.

In chart-based navigation, lines of position (whether celestial or terrestrial) can be easily advanced or retired over changes to course and speed (see Bowditch [2], pp. 130–132). The assumption is simply made that the difference between a vessel’s true position and its estimated position—the error in position—remains constant, in azimuth and distance, as the vessel moves, despite course and speed changes. The procedure for advancing a line of position is thus no more complicated when several voyage legs are involved than when there is only a single leg to consider. A popular mathematical approach to celestial sight reduction [3,4] is a direct mathematical translation of chart-based navigation, and it adopts the same assumption for combining observations spanning multiple legs.

However, as pointed out in [5], even when only one leg is involved, this assumption cannot be rigorously true, and it is often not even approximately true. A vessel’s estimated course and speed over bottom may be considerably in error due to components of current and wind not taken into account. In practice, then, the error in position changes with time. The situation is complicated further by changes to direction or speed, which modify the net force of the wind on the vessel. So not only is the basic assumption (constant positional error) dubious, but so is its first derivative (constant rate of change of positional error) when multiple legs are involved.

The development presented in [1] assumed at the outset that the observer’s estimated course and speed are probably not accurate, so that the error in position is not constant. That algorithm allows for a simultaneous solution for latitude, longitude, course, and speed. However, the algorithm is based on the geometry of a single rhumb-line leg—that is, the course and speed are assumed constant. This paper explores how
the approach in [1] can be generalized for the multiple-leg case. The multiple-leg algorithm presented here, although developed for rhumb-line tracks and celestial navigation, is applicable to any kind of track and any set of observations in which a single observable is a known function of the observer’s instantaneous latitude and longitude.

Single-Leg Solution

The algorithm presented in [1] is a least-squares solution for a vessel’s latitude and longitude at a specific time, along with its course and speed (assumed constant). We assume that initially we know the vessel’s track reasonably well. Errors of several degrees in position or course or several knots in speed are routinely handled, and larger errors usually only require additional iterations for convergence. What we are solving for are corrections to our \textit{a priori} estimates of these four quantities. The equation of condition for the least-squares solution, which is computed for each observation, is:

\[ a = \left( \frac{\partial H_c}{\partial \phi} \right) \Delta \phi_0 + \left( \frac{\partial H_c}{\partial \lambda} \right) \Delta \lambda_0 + \left( \frac{\partial H_c}{\partial C} \right) \Delta C + \left( \frac{\partial H_c}{\partial S} \right) \Delta S \]

where \( a \) is the altitude intercept \((a = H_o - H_c)\),
\( H_o \) is the observed altitude,
\( H_c \) is the computed altitude,
\( \phi \) is the estimated latitude for the time of observation,
\( \lambda \) is the estimated longitude for the time of observation,
\( \phi_0 \) is the estimated latitude for the time of the fix,
\( \lambda_0 \) is the estimated longitude for the time of the fix,
\( C \) is the course of the observer’s vessel,
\( S \) is the speed of the observer’s vessel,
\( f \) is the rhumb-line sailing formula for latitude, and
\( g \) is the rhumb-line sailing formula for longitude.

This equation expresses the altitude intercept \( a \) in terms of small corrections to the estimated latitude, longitude, course, and speed, respectively denoted \( \Delta \phi_0 \), \( \Delta \lambda_0 \), \( \Delta C \), and \( \Delta S \). These latter four quantities are unknowns to be determined, and once their values are known, we can correct our estimate of the vessel’s track. The corrections to latitude and longitude have 0 subscripts to denote that they apply to the specific time, \( t_0 \), for which the fix is desired. All angles, including latitude and longitude, are expressed in radians.

The quantities within parentheses in equation (1) are the coefficients of the unknowns. These coefficients, along with the altitude intercept \( a \), must be numerically evaluated for each observation. To do that, we need algebraic expressions for the partial derivatives. There are ten partial derivatives that appear:

\[ \frac{\partial H_c}{\partial \phi}, \frac{\partial H_c}{\partial \lambda}, \frac{\partial f}{\partial \phi}, \frac{\partial f}{\partial \lambda}, \frac{\partial g}{\partial \phi}, \frac{\partial g}{\partial \lambda}, \frac{\partial g}{\partial C}, \frac{\partial g}{\partial S} \]

These are obtained from three formulas: the equation for \( H_c \) as a function of \( \phi \) and \( \lambda \); the sailing formula for latitude, represented by the function \( f \); and the sailing formula for longitude, represented by the function \( g \). The sailing formulas are functions that together provide the position of the vessel as a function of time \( t \); they involve the parameters \( C, S, \phi_0, \) and \( \lambda_0 \) (the sailing formulas are derived in [6]). Algebraic expressions for all the partials needed above are given in the Appendix to [1].

For a single-leg solution, the mathematical procedure can be summarized as follows. First, the time \( t_0 \) for the fix is chosen. Initial estimates of the values of \( \phi_0, \lambda_0, C, \) and \( S \) are made for time \( t_0 \). The sailing formulas \( f \) and \( g \) then allow the instantaneous latitude, \( \phi \), and longitude, \( \lambda \), to be computed for any other time \( t \). For each observation, therefore, an estimate of \( \phi \) and \( \lambda \) is made. The sextant altitude, \( h_s \), is reduced...
to an observed altitude, \(H_0\), in the usual way. An almanac or ephemeris routine is then used to provide the
celestial coordinates (GHA and Dec) of the observed body, and \(H_c\) and \(a\) are computed for the observation.
Using the expressions for the partials given in [1], the coefficients of the unknowns in equation (1) can be
computed. To include the observation in the least-squares solution, the coefficients are added as a new row
in the design matrix, and \(a\) is added to the column vector of measurements. After all observations have been
processed in this way, the least-squares solution is computed, yielding values for \(\Delta \phi_0\), \(\Delta \lambda_0\), \(\Delta C\), and \(\Delta S\).
These are then used to correct the original estimates of \(\phi_0\), \(\lambda_0\), \(C\), and \(S\) for time \(t_0\). The corrected values
of \(\phi_0\) and \(\lambda_0\) define the fix. The whole process can be reiterated if necessary, using the new values of \(\phi_0\), \(\lambda_0\),
\(C\), and \(S\) as the basis for the computations. Details, including a numerical example, are given in [1]. For a
description of least-squares techniques, see any text on scientific data analysis, for example, [7,8].

Equation (1) can be applied beyond the case of celestial navigation if we simply generalize the meanings
of several variables. \(H_0\) and \(H_c\) can be regarded as the observed and computed values, respectively, of any
scalar quantity that can be measured while underway and that is a function of the observer’s instantaneous
latitude and longitude. For example, range to a known point would be such a quantity. Then \(a = H_0 - H_c\)
becomes simply the “observed minus computed” residual of this quantity. As long as we can compute
\(a\), \(\partial H_c/\partial \phi\), and \(\partial H_c/\partial \lambda\) for each observation (and the geometry of the observations is not degenerate),
equation (1) applies. The development presented below does not depend on particular meanings of \(H_0\), \(H_c\),
\(a\), or the partial derivatives \(\partial H_c/\partial \phi\) and \(\partial H_c/\partial \lambda\).

General Considerations for Multiple-Leg Tracks

When we have observations spread over more than one leg, the conditional equation gains additional
terms corresponding to the added degrees of freedom in the problem. That is, the geometry of the problem
becomes more complex and can be described only with additional parameters, some of which we must solve
for. We will consider a new voyage leg to begin with either a course change or a speed change (or both)
at a known time. We model these changes as instantaneous, and we can ignore the finite turning radius of
the vessel if (1) no observations are made during the turn, and (2) the turning radius is short compared
with the length of the straight portions of the vessel’s track. In the most general case, each leg has both
course and speed independent of the course and speed on any other leg. (This allows for the case where a
change of either course or speed alters the interaction of wind and current on the vessel and affects the other
parameter.) Just as in the single-leg case, we assume that, initially, we know the vessel’s track reasonably
well (errors not exceeding a few degrees in position or course and a few knots in speed), and that what we
need to solve for are corrections to our starting estimates of the relevant parameters.

To cover the multiple-leg case, some changes to our mathematical notation are necessary. We will use
subscripts to designate specific legs. The first leg will be denoted by subscript 1. This leg begins at time \(t_1\),
when the vessel is at position \((\phi_1, \lambda_1)\), sailing course \(C_1\) at speed \(S_1\). The second leg begins at time \(t_2\) when
the vessel is at position \((\phi_2, \lambda_2)\); the new course and speed are \(C_2\) and \(S_2\). The third begins at time \(t_3\), and
so on. We assume that we know the times \(t_j\) exactly, and that we start with reasonable estimates for the
other quantities.

We have used the symbols \(f\) and \(g\) to represent the sailing formulas for rhumb-line tracks, which
respectively provide the latitude and longitude of the vessel as a function of time. For the multiple-leg case,
we must use the symbols \(f_1\) and \(g_1\) to represent the sailing formulas to be used for leg 1, \(f_2\) and \(g_2\) to
represent the sailing formulas to be used for leg 2, etc. The algebraic form of the sailing formulas is, of
course, the same for all legs; it is just the parameter values used in the formulas that are different for each
leg. We will continue to use the symbols \(f\) and \(g\) (without subscripts) to represent the generic form of the
sailing formulas. The values of five parameters in these formulas effectively define the functions \(f_j\) and \(g_j\)
for each leg \(j\). The parameters are the time \(t_j\), at which the leg begins, the latitude \(\phi_j\) and longitude \(\lambda_j\) of
the vessel at time \(t_j\), the course \(C_j\), and the speed \(S_j\). For each leg \(j\) we have

\[
\phi(t) = f_j = f(t - t_j, \phi_j, \lambda_j, C_j, S_j) \\
\lambda(t) = g_j = g(t - t_j, \phi_j, \lambda_j, C_j, S_j)
\]

\[(2)\]
The initial point of the leg (position \((\phi_j, \lambda_j)\) at time \(t_j\)) thus serves as a reference point for the sailing formulas for the leg. We have made the reference point of each leg to be the initial point, but that is a requirement only for the second and succeeding legs in a multiple-leg case; for the first (or only) leg, the reference point can be anywhere along the leg.

It should be noted that the functional dependence of the two sailing formulas on the parameters shown in equation (2) is implicit; the set of parameters used explicitly in the two formulas is somewhat different. As presented in [1] and [6], both formulas contain auxiliary variables that need to be expanded before the dependence of these formulas on the parameter set shown above becomes evident.

The naive approach to the multiple-leg problem would be to simply take equation (1) and generalize it to cover N legs, using the notation just introduced:

\[
a_{ik} = \sum_{j=1}^{N} \left[ \left( \frac{\partial Hc}{\partial \phi_j} \frac{\partial f_k}{\partial \phi} + \frac{\partial Hc}{\partial \lambda_j} \frac{\partial g_k}{\partial \phi} \right) \Delta \phi_j + \left( \frac{\partial Hc}{\partial \phi_j} \frac{\partial f_k}{\partial \lambda_j} + \frac{\partial Hc}{\partial \lambda_j} \frac{\partial g_k}{\partial \lambda_j} \right) \Delta \lambda_j \right.

\left. + \left( \frac{\partial Hc}{\partial \phi_j} \frac{\partial f_k}{\partial C_j} + \frac{\partial Hc}{\partial \lambda_j} \frac{\partial g_k}{\partial C_j} \right) \Delta C_j + \left( \frac{\partial Hc}{\partial \phi_j} \frac{\partial f_k}{\partial S_j} + \frac{\partial Hc}{\partial \lambda_j} \frac{\partial g_k}{\partial S_j} \right) \Delta S_j \right]
\]  

(3)

where the subscript \(k\) denotes the leg on which the observation was taken, \(a_{ik}\) represents the altitude intercept for the \(i\)th observation on leg \(k\), and the summation is over all N legs in the problem. There are 4N free parameters to be determined: \(\Delta \phi_j\), \(\Delta \lambda_j\), \(\Delta C_j\), and \(\Delta S_j\) for \(j = 1\) through \(N\). The partial derivatives of the sailing formulas that appear in equation (3) contain subscripts. The subscript in the “numerator”, \(k\), represents the leg number of the observation being processed and the subscript in the “denominator”, \(j\), represents the leg number of a particular unknown.

In this construction of the problem, each leg is independent of the others, and there is no requirement that the legs be continuous. With independent legs, only observations taken on a particular leg contribute to the parameters for that leg. That is because the sailing formulas for a particular leg depend only on parameters relating to that leg, and therefore the partial derivatives of the sailing formulas are zero if \(j \neq k\). Therefore, in equation (3), as \(j\) cycles from 1 to \(N\), the coefficients of all the unknowns are zero except when \(j = k\), so that an observation has no effect except on parameters relating to its own leg. When \(j = k\), the partials are evaluated from the single-leg formulas given in [1]. What we have done, therefore, is set up a single least-squares solution for a problem that could be handled as \(N\) individual least-squares solutions, one for each leg. The values of the unknowns that we solve for will be the same regardless of which approach is taken.

Of course, the idea that a multiple-leg voyage consists of a series of independent legs does not correspond to the real problem. The courses and speeds may be independent, but each leg must be continuous with its neighbors. Because we are modeling each leg change as instantaneous, continuity is required only in position, not in motion. The requirement that adjacent legs be continuous defines a set of constraints on the solution, and constraints always reduce the number of free parameters in a problem. Formal methods have been developed to deal with constrained least-squares problems, but the multiple-leg problem can be attacked more easily. In the next section, we will abandon equation (3) and take another approach to the problem.

Algorithm for Multiple-Leg Tracks

A viable solution to the real multiple-leg problem must explicitly or implicitly deal with the requirement of continuity at the leg intersections. The mathematical condition is that, for all legs beyond the first, the point at the start of leg \(j\) must be identical to that at the end of leg \(j - 1\). At the start of leg \(j > 1\), the vessel’s coordinates \((\phi_j, \lambda_j)\) are therefore not free parameters. Only on the first leg are the coordinates of the reference point free parameters. Given the location of that reference point, the time of each course or speed change, and the course and speed values on each leg, the vessel’s track is completely determined. Since
all the times are known, for N legs, there are 2N+2 free parameters in the problem (rather than 4N, as in equation (3) above). We start with estimates of their values and seek to correct those estimates. The two quantities \( \phi_1 \) and \( \lambda_1 \), which define the position of the vessel at the reference point of the first leg, represent the fix. The other free parameters of the problem are the course and speed along each leg. The conditional equation for this case must therefore take the form

\[
a_{ik} = \left( \frac{\partial H_c}{\partial \phi} \frac{\partial f_k}{\partial \phi_1} + \frac{\partial H_c}{\partial \lambda} \frac{\partial g_k}{\partial \phi_1} \right) \Delta \phi_1 + \left( \frac{\partial H_c}{\partial \phi} \frac{\partial f_k}{\partial \lambda_1} + \frac{\partial H_c}{\partial \lambda} \frac{\partial g_k}{\partial \lambda_1} \right) \Delta \lambda_1
\]

\[
+ \sum_{j=1}^{N} \left( \frac{\partial H_c}{\partial \phi} \frac{\partial f_k}{\partial C_j} + \frac{\partial H_c}{\partial \lambda} \frac{\partial g_k}{\partial C_j} \right) \Delta C_j + \left( \frac{\partial H_c}{\partial \phi} \frac{\partial f_k}{\partial S_j} + \frac{\partial H_c}{\partial \lambda} \frac{\partial g_k}{\partial S_j} \right) \Delta S_j
\]

where the notation is the same as for equation (3). This equation must be evaluated numerically for each observation, and the observations are taken in chronological order so that all the observations from a given voyage leg \( k \) are processed before any observations from the next leg.

In equation (4), as in equations (1) and (3), the coefficients of the unknowns are composed of linear combinations of partial derivatives. The issue is how to evaluate these partial derivatives as the observations from each leg are processed. These partial derivatives are of two types. The partials of the observable \( H_c \) with respect to the instantaneous position of the vessel (\( \partial H_c/\partial \phi \) and \( \partial H_c/\partial \lambda \)) are straightforward to evaluate; if \( H_c \) is celestial altitude, the expressions can be taken from [1]. The partials of the sailing formulas \( f_k \) and \( g_k \) are more difficult to deal with, because they describe the relationship between the ship’s instantaneous position and all the free parameters in the problem (\( \phi_1 \) and \( \lambda_1 \) as well as \( C_j \) and \( S_j \) for all \( j \)).

The sailing formula partials contain subscripts: \( k \) in the “numerator” represents the leg number of the current observation and \( j \) in the “denominator” represents the leg number of a particular unknown. (In the top line of equation (4), \( j = 1 \).) Within each evaluation of equation (4) (each observation), \( k \) remains fixed but \( j \) runs over all the legs in the problem. In evaluating the sailing-formula partials, we therefore have three cases to consider: \( j < k, j = k, \) and \( j > k \). Keeping in mind the meanings of \( j \) and \( k \), we recognize that for \( j > k \), the sailing formula partials must be zero, reflecting the fact that the ship’s current computed position cannot depend on the parameters of future legs. For \( j = k \), the partials must be the same as in the single-leg case, and the expressions from [1] can be directly used. The \( j < k \) case is the most complicated, because these partials must reflect the fact that the ship’s computed position does depend on the parameters of past legs, propagated through the constraints at the leg intersections. Most of Appendix A deals with this case.

Thus, the net effect of the partials of the sailing formulas on equation (4) is that each observation contributes to determining not just the course and speed on its own leg \( k \) but also those of all preceding legs. However, the future is indeterminate, and observations cannot provide any information on the unknowns relating to legs that have not yet occurred (they may not occur). All observations contribute to determining the coordinates of the reference point on the first leg, which serves as the fix for the multiple-leg problem.

In Appendix A, an algorithm for the evaluation of the sailing formulas partials that appear in equation (4) is presented. The algorithm is quite straightforward in that all that is done for the \( j < k \) case is to implicitly fold the continuity constraints into the sailing formulas, the functions \( f_k \) and \( g_k \) for leg \( k \). Then, new expressions for the partial derivatives of \( f_k \) and \( g_k \) are immediately obtained using the chain rule. These expressions amount to recurrence relations. Partials computed for each leg are built on partials computed for previous legs (a process that follows logically from the nature of the problem). Some care with mathematical bookkeeping is necessary. However, the advantage of this scheme is that, if the observations are processed in chronological order, no calculations are required beyond those needed for the single-leg case, except trivial multiplications and additions. No changes are required in the least-squares procedure itself. Appendix A describes the procedure in detail. Because it represents a modification to the single-leg case, the algorithm is not difficult to implement in computer code.

In the development of the multiple-leg case presented here, the fix is always on the first leg. In practice, what is of interest is not really the vessel’s position on the first leg, but the last, which is the leg that
the vessel is currently sailing. It may seem as if the problem should be reversed. In fact, we can do just that—the problem is symmetric in time and the vessel can, mathematically, be sailed backwards as well as forwards. Therefore, what we have been calling the “first leg” can actually be the last and what we called the “initial point” of each leg can actually be the final point. The problem has been described in a manner that keeps the development and terminology as straightforward as possible. This allows us to visualize the vessel as moving forward in time, to discuss causes and effects in a natural order, and to refer to leg \( j + 1 \) as the “subsequent” or “next” leg. However, when the algorithm presented here is used for real problems, the procedure can be implemented in a time-reversed fashion to provide information of practical use.

Sample Calculation

A numerical example using this algorithm is presented below. A set of 12 artificial sextant observations (hs values), spanning 3 legs of a hypothetical voyage (4 observations per leg), was reduced using the algorithm described in this paper. The solution yielded a position fix for a single specified time in the final leg and course and speed estimates for all legs. The artificial observations were generated by a computer program that numerically integrated a hypothetical ship’s course, consisting of 3 rhumb-line tracks, as shown in Table 1 (north latitudes and east longitudes are positive).

The data in Table 1, and any positions derived from them, constitute “truth” for this case. The latitude and longitude listed for the beginning of legs B and C were computed from the data for the previous leg; that is, the legs meet at these points and the changes to course and speed were assumed to be instantaneous. Astronomical positions of the celestial bodies chosen were computed that are consistent with those in the 1996 *Nautical Almanac* and transformed to local altitudes. Atmospheric refraction was included but the height of eye was considered to be zero, and the time scale UT1 was assumed to be identical to UTC (that is, DUT1=UT1–UTC=0). Random errors with a 0.7 arcmin standard deviation were added to the calculated hs values. The artificial observations, for 30-31 August 1996 (UTC), are given in Table 2.

All of the Sun and Moon observations apply to the lower limb. The star and planet observations represent twilight observations; the two Moon observations represent night observations. The Moon’s phase was 0.92 (age 17 days).

Once computed and stored in a file, these artificial observations were used as input to a separate computer program that implemented the algorithm described in this paper. This second program was given the incorrect data on the ship’s position and motion listed in Table 3.

The dates and times shown in Table 3 are the same as in Table 1, but the course and speed values, as well as the position of the first point of leg A, are considerably different. Just as in Table 1, the latitude and longitude listed in Table 3 for the beginning of legs B and C are computed from the data listed for the previous leg. Clearly, this track (Table 3) is a rather poor approximation to the true track (Table 1). The test of the algorithm is whether, given only the 12 observations (Table 2), it can determine the true track of the vessel, limited only by the error in the observations. The date and time for the desired fix were chosen to be 1 Sep 1996 at 07:30:00 UTC, which is on leg C, 8.4 hours after the last observation. In addition to the latitude and longitude for that time, course and speed for all 3 legs were to be determined. Based on the incorrect data on the ship’s track it was given, the second program computed the estimated latitude and longitude for the time of the fix to be (+48.490°, −37.280°). It also computed the data in Table 4 for the 12 observations.

In Table 4, the altitude intercept, a, is Ho − Hc and positive values indicate “toward.” The Ho and Hc values are topocentric and, for the Sun and Moon, they refer to the lower limb. The large a values are a result of the poor data on the ship’s track that the program was given, that we hope to correct.

As described previously, the algorithm described in this paper will usually be implemented in a time-reversed sense. The program followed this strategy, working backwards through the observations and effectively treating leg C, containing the fix, as the “first” leg. In recognition of this strategy, and in order to maintain consistency with equation (4), the following notation will therefore be used:

\[
\text{Leg A → Leg 3: Course } C_3, \text{ Speed } S_3
\]
\[
\text{Leg B → Leg 2: Course } C_2, \text{ Speed } S_2
\]
\[
\text{Leg C → Leg 1: Course } C_1, \text{ Speed } S_1, \text{ Fix Coordinates } \phi_1, \lambda_1
\]

As it processed each observation, the program computed the values of the coefficients of all the unknowns in equation (4). It sent these coefficient values, along with the value of a, to a standard least-squares routine.
All the observations were given equal weight. After all 12 observations had been processed in this way, the least-squares solution was formed. The results are given in Table 5, which lists the corrections to the parameters describing the ship’s track.

The second column in Table 5 indicates the number of observations contributing to each parameter. Table 5 shows rather large corrections to the parameter values, as we expect from the crudeness of the track data that the program used. The mean error of unit weight of the solution was computed to be 0.8 arcmin. If we add the parameter values from Table 5 to the estimated (incorrect) data on the ship’s track, we obtain the final results of the entire process, summarized in Table 6.

The units used in Table 6 are degrees and knots, as in the previous tables. “Error” simply refers to the difference solution–truth. Obviously a great improvement in the data on the ship’s track was made. Of course, in a real situation, “Truth” would not be known—the question at this point would be whether another iteration of entire procedure would be advisable, using the updated values of the parameters describing the ship’s track given in Table 6. In fact, the program did perform two iterations of the algorithm, and the results given in Tables 5 and 6 reflect the sum of the corrections obtained from the two iterations. If the solution is reliable, the iterations will converge rapidly; that is, the parameter corrections from a second or third iteration will all be much smaller than those from the previous iteration. That was the case here.

The algorithm did recover the ship’s true track, although the fix coordinates are perhaps not as accurate as we might desire. The error in the fix position is 2.5 nmi, even though the observations had a scatter of 0.7 arcmin. This example is adversely affected by the small number of observations involved—there are only $1\frac{1}{2}$ times as many observations as there are parameters, leaving only 4 degrees of freedom. The parameter correlation matrix from the solution showed a 0.96 correlation between $\Delta \phi_1$ and $\Delta C_1$, indicating that the geometry of the observations does not allow a clean separation of the effects of these errors. Such problems are not uncommon in cases with so few observations. Generally, at least a half-dozen observations on each leg, well spread out in time, should be used. In one scenario tested, adding just 4 more observations to this example reduced the error in the fix to less than 1 nmi. The extra observations not only doubled the number of degrees of freedom in the problem but also improved its geometry.

In any event, the multiple-leg algorithm described in this paper may provide the best answers attainable for the 12-observation case we have been considering. For example, if we try something more conventional, and process only the observations in leg 1 (leg C), we obtain the results in Table 7.

Two solutions for leg 1 (leg C) are given in Table 7: above the line, only the latitude and longitude of the fix have been solved for; below the line, course and speed values have also been determined (the second solution has no degrees of freedom). Clearly, neither is satisfactory—the errors in the fix position are 27.6 and 16.1 nmi, respectively. The difficulty in treating leg 1 alone is that the observations represent a group of sights taken within a 1-hour period during evening twilight. Since the course and speed are not well known, and cannot be accurately determined using these observations, the extrapolation to the time of the fix fails. In this case, the use of observations from the previous legs can add substantial information to the process, providing a reasonable determination of the course and speed values for leg 1 (the final leg), and allowing a relatively accurate extrapolation of the ship’s position forward.

What would happen to our 3-leg, 12-observation case if the observations were substantially better (or worse) than those listed in Table 2? We can easily change the random scatter in the artificial observations and run through the entire procedure again. The results of this experiment are summarized in Table 8, the body of which shows the error of each parameter (solution–truth), in the units we have been using, as a function of observational scatter.

</tbody>
</table>

There are no surprises in Table 8; it simply indicates that the errors in the parameters solved for are directly proportional to the scatter in the observations.

Use of the Multiple-Leg Algorithm

The algorithm outlined above and detailed in Appendix A has been implemented in software for celestial navigation. It was produced by the U.S. Naval Observatory for Navy shipboard use [9]. This software is currently operational in the fleet. The algorithm has been extensively tested using artificial observations generated by independent programs, where “truth” can be known absolutely and controlled. The algorithm is accurate and remarkably robust across a wide variety of voyage track scenarios.

The algorithm cannot, however, be applied blindly, and the distribution of the observations in time and azimuth should be considered before proceeding. As the sample calculation above shows, it is advisable for there to be at least a half-dozen observations on each leg. However, valid solutions can sometimes be formed with fewer observations, or even when one or more legs are “empty.” The example above also shows the utility of the algorithm in establishing a mathematical linkage between the legs that allows observations from
subsequent (previous) legs to contribute to the solution on the first (last) leg—which includes the adjustment
to the fix coordinates. It is difficult to provide hard and fast \textit{a priori} rules for the algorithm’s application
that apply in all cases. As in any least-squares procedure, the parameter correlation matrix (obtained from
the variance-covariance matrix) from the solution should be examined to determine whether the solution
is reliable. When that is not the case, it may be inadvisable to use the algorithm in its fullest generality
as presented above; course and speed corrections for certain legs may be excluded. In such cases, in the
summation term of equation (4), the \( j \) for any leg can simply be skipped over and the corresponding \( \Delta C_j \)
and \( \Delta S_j \) not included in the solution. If the distribution of observations is very sparse, the entire summation
term of equation (4) can be omitted, and the solution confined to \( \Delta \phi_1 \) and \( \Delta \lambda_1 \), that is, only corrections to
the fix coordinates are computed. Clearly, however, the algorithm is most useful, and reliable, when there is
a good distribution of observations on each leg. In the case of celestial navigation, an automated observing
system might be required to provide the number and accuracy of the observations needed.

The algorithm is quite general. As previously noted, equation (4) is not limited to celestial observations—
\( H_c \) can represent any observable which is a known function of latitude and longitude. The only requirement
is that the functions \( f \) and \( g \) provide the coordinates of the vessel as a function of time and the latitude,
latitude, course, and speed at the beginning of the leg.

The algorithm might be useful even when a ship is nominally holding a fixed course and speed. If
significant changes in current or wind occur, a single rhumb line may not adequately model the ship’s track
over bottom. In such cases, the ship’s motion might be approximated by a series of rhumb-line legs, and the
algorithm given in this paper would then be applicable.

Finally, in [1], the navigation problem for vessels on the surface of the Earth was described as being anal-
ogous to the orbit determination problem for bodies in the solar system. That paper derived the conditional
equation for the single-leg navigation problem, reproduced here as equation (1), from considerations similar
to those used by astronomers for the orbit problem. It may seem as if the multiple-leg navigation problem
addressed in this paper has no analog in orbit theory, but that is not so. Spacecraft trajectories are adjusted
by rocket firings, and the orbits of asteroids, comets, and spacecraft are perturbed by close approaches to
massive bodies. In most of these cases the agent of change (a rocket burn or close gravitational encounter) is
a transient phenomenon. An approximate treatment of such a problem, adequate for many purposes, would
be to consider the “before” and “after” trajectories to meet at a point in space where the motion of the
body instantaneously changes. Thus, even when orbits in the solar system are considered, we have situations
that are quite similar to the multiple-leg navigation case. The strategy for dealing with the multiple-leg
navigation problem described in this paper could be generalized to the orbit-determination problem as well.

Conclusion

The running fix—the determination of position at sea using observations taken over extended time
spans—is a common navigational problem. Traditional chart-based techniques advance or retire lines of
position to a common time. The technique works best when the vessel’s motion is constant, but it is also
applied across changes to course or speed, that is, to multiple-leg tracks. A commonly used mathematical
development of celestial navigation mimics the chart-based scheme. The weakness of this approach to the
running-fix problem is that it is based on the assumption that the difference between a vessel’s estimated
and true positions remains constant in two dimensions as the ship moves. The notion that a ship’s positional
error is constant is unlikely to be true, even approximately, except over very short periods, and any change
to course or speed only complicates the situation.

An algorithm has been presented in this paper that allows celestial or other observations made over
several voyage legs to be combined into a single solution for all relevant sailing parameters: the latitude
and longitude of one point on the track and the course and speed along each leg. In this algorithm, the
error in position is assumed to change, and its rate of change is assumed to be different along each leg. The
algorithm is conceptually simple, uses ordinary least-squares procedures, makes efficient use of the available
observations, and is relatively easy to implement in computer code.

Appendix A

Evaluating the Partial Derivatives of the Sailing Formulas in the Multiple-Leg Case

Equation (4) in the main part of the paper is the conditional equation for a least-squares solution for the unknowns of the multiple-leg navigation problem. To use it, we need to be able to numerically evaluate the quantities within the parentheses in the equation, which are the coefficients of the unknowns. Equation (4) is evaluated for each observation. It is advantageous to take the observations in chronological order, so that all observations on a given leg are processed before any observations on the next leg.

The coefficients of the unknowns in equation (4) consist of linear combinations of various partial derivatives. As mentioned in the main text, the partials that appear are either partials of the observable $H_c$ or partials of the sailing formulas $f$ and $g$. For celestial observations, expressions for the partial derivatives $\partial H_c / \partial \phi$ and $\partial H_c / \partial \lambda$ are given in [1] and will not be discussed further here. For the multiple-leg case, the quantities that need special attention are the partial derivatives of the sailing formulas, for example, $\partial f_k / \partial \phi_1$ or $\partial g_k / \partial C_j$. These appear in equation (4) in the generic form $\partial y_k / \partial x_j$, where $y$ represents either the function $f$ or $g$, and $x$ represents any of the four parameters $\phi, \lambda, C$, or $S$. We will refer to these partial derivatives simply as the “sailing partials.” The subscript $k$ represents the leg number of the current observation, while $j$ represents the leg number of a particular unknown. In each evaluation of equation (4), $k$ remains fixed but $j$ runs over all legs in the problem.

There are three fundamental points to be noted in evaluating equation (4):

1. Each partial derivative that appears in equation (4) is numerically evaluated for the time and estimated position of the observation being processed, using the current best estimates of the values of the parameters of the problem.

2. When the subscripts in the “numerator” and “denominator” of the sailing partials are the same, that is, when $j = k$, the partials correspond to those of the single-leg case. The expressions from the appendix to [1] can be used directly, although the notation is somewhat different. For example, $\partial g_2 / \partial \phi_2$ is evaluated using the equation from [1] for $\partial g / \partial \phi_1$, applied to leg 2.

3. The summation in the second line of equation (4) effectively ends at $j = k$, since all the sailing partials are zero when $j > k$, for reasons stated in the main body of the paper.

The major issue addressed in this appendix is the evaluation of the sailing partials in equation (4) when $j < k$. These occur in the computation of the coefficients of unknowns relating to legs preceding the one on which the observation was taken. To facilitate the computation of these partials, we will add an artificial observation at the end of each leg; that is, for leg $j$ the added computation point is at $t = t_{j+1}$. We compute all the sailing partials that appear in equation (4) for this point just as if it were an actual observation at the very end of the leg. The values of these partials are stored for future reference. This point is not included in the solution since it is not an actual observation (we have no value for $a_{ik}$). The artificial observation is processed this way for each leg except the final one, where it is superfluous. The utility of these artificial observations will soon become evident.

First Leg. The sailing formulas for the first leg, which apply to times $t$ where $t_1 \leq t \leq t_2$, can be represented as

\[
\phi(t) = f_1 = f(t - t_1, \phi_1, \lambda_1, C_1, S_1) \\
\lambda(t) = g_1 = g(t - t_1, \phi_1, \lambda_1, C_1, S_1)
\]

(A1)

For observations on the first leg, where $k = 1$, we only have to deal with $j = 1$ since the sailing partials are all zero for $j > k$. Since the only subscript we encounter in either “numerator” or “denominator” is 1, all the observations on the first leg are processed just as in the single-leg problem.

Second Leg. The sailing formulas for the second leg, which apply to times $t$ where $t_2 \leq t \leq t_3$, are:

\[
\phi(t) = f_2 = f(t - t_2, \phi_2, \lambda_2, C_2, S_2) \\
\lambda(t) = g_2 = g(t - t_2, \phi_2, \lambda_2, C_2, S_2)
\]

(A2)
However, there is a constraint on the point \((\phi_2, \lambda_2)\), which is the start of leg 2: it is also the end of leg 1. That is, at \(t = t_2\), we have \(f_2 = f_1\) and \(g_2 = g_1\). More explicitly,

\[
\phi_2 = \phi(t_2) = f_2\bigg|_{t_2} = f_1\bigg|_{t_2} = f(t_2 - t_1, \phi_1, \lambda_1, C, S)
\]

\[
\lambda_2 = \lambda(t_2) = g_2\bigg|_{t_2} = g_1\bigg|_{t_2} = g(t_2 - t_1, \phi_1, \lambda_1, C, S)
\]

(A3)

where the vertical bar means “evaluated at.”

For observations on the second leg, where \(k = 2\), we have to deal with \(j = 1\) and \(2\); the sailing partials are all zero for \(j > k\).

**Partials for \(\Delta \phi_1\) and \(\Delta \lambda_1\).** To obtain expressions for the sailing partials needed in the first line of equation (4), we substitute the expressions for \(\phi_2\) and \(\lambda_2\) from the right side of equations (A3) into equations (A2), then differentiate using the generalized chain rule. The results are:

\[
\begin{align*}
\frac{\partial f_2}{\partial \phi_1} & = \frac{\partial f_2}{\partial \phi_2} \frac{\partial f_1}{\partial \phi_1} + \frac{\partial f_2}{\partial \lambda_2} \frac{\partial g_1}{\partial \phi_1} \\
\frac{\partial f_2}{\partial \lambda_1} & = \frac{\partial f_2}{\partial \phi_2} \frac{\partial f_1}{\partial \lambda_1} + \frac{\partial f_2}{\partial \lambda_2} \frac{\partial g_1}{\partial \lambda_1} \\
\frac{\partial g_2}{\partial \phi_1} & = \frac{\partial g_2}{\partial \phi_2} \frac{\partial f_1}{\partial \phi_1} + \frac{\partial g_2}{\partial \lambda_2} \frac{\partial g_1}{\partial \phi_1} \\
\frac{\partial g_2}{\partial \lambda_1} & = \frac{\partial g_2}{\partial \phi_2} \frac{\partial f_1}{\partial \lambda_1} + \frac{\partial g_2}{\partial \lambda_2} \frac{\partial g_1}{\partial \lambda_1}
\end{align*}
\]

(A4)

On the right sides of equations (A4), the partials of \(f_2\) and \(g_2\) \((\partial f_2/\partial \phi_2, \text{ etc.})\), the first factors in each term) are evaluated for the particular time of the observation being processed, and are computed from the single-leg formulas just as if leg 2 were the only leg in the problem. However, the partials of \(f_1\) and \(g_1\) \((\partial f_1/\partial \phi_1, \text{ etc.})\), the second factors in each term) are evaluated for time \(t = t_2\) (as required by equation (A3)), so their values have already been computed—they are the partials computed for the artificial observation at the end of leg 1.

**Partials for \(\Delta C_1\) and \(\Delta S_1\).** Similarly, we differentiate equations (A2), with \(\phi_2\) and \(\lambda_2\) substituted from equations (A3), to obtain the sailing partials needed for the second line of equation (4) when \(j = 1\):

\[
\begin{align*}
\frac{\partial f_2}{\partial C_1} & = \frac{\partial f_2}{\partial \phi_2} \frac{\partial f_1}{\partial C_1} + \frac{\partial f_2}{\partial \lambda_2} \frac{\partial g_1}{\partial C_1} \\
\frac{\partial f_2}{\partial S_1} & = \frac{\partial f_2}{\partial \phi_2} \frac{\partial f_1}{\partial S_1} + \frac{\partial f_2}{\partial \lambda_2} \frac{\partial g_1}{\partial S_1} \\
\frac{\partial g_2}{\partial C_1} & = \frac{\partial g_2}{\partial \phi_2} \frac{\partial f_1}{\partial C_1} + \frac{\partial g_2}{\partial \lambda_2} \frac{\partial g_1}{\partial C_1} \\
\frac{\partial g_2}{\partial S_1} & = \frac{\partial g_2}{\partial \phi_2} \frac{\partial f_1}{\partial S_1} + \frac{\partial g_2}{\partial \lambda_2} \frac{\partial g_1}{\partial S_1}
\end{align*}
\]

(A5)

The partials of \(f_2\) and \(g_2\) on the right side of equation (A5) are the same as those on the right side of equation (A4). The partials of \(f_1\) and \(g_1\) are evaluated for time \(t = t_2\), the end point of leg 1, so their values have also been previously computed.

**Partials for \(\Delta C_2\) and \(\Delta S_2\).** For the second line of equation (4) when \(j = 2\), we encounter only partials where the “numerator” and “denominator” have the same subscript (i.e., \(j = k = 2\)). These are evaluated for each observation from leg 2 just as if it were a single-leg case.
Third Leg. The sailing formulas in latitude and longitude for leg 3 can be represented as

\[
\phi(t) = f_3 = f(t - t_3, \phi_3, \lambda_3, C_3, S_3)
\]
\[
\lambda(t) = g_3 = g(t - t_3, \phi_3, \lambda_3, C_3, S_3)
\]

(A6)

We have the usual constraint on the point \((\phi_3, \lambda_3)\), which is the start of leg 3, but also the end of leg 2:

\[
\phi_3 = \phi(t_3) = f_3|_{t_3} = f(t_3 - t_2, \phi_2, \lambda_2, C_2, S_2)
\]
\[
\lambda_3 = \lambda(t_3) = g_3|_{t_3} = g(t_3 - t_2, \phi_2, \lambda_2, C_2, S_2)
\]

(A7)

For observations on the third leg, where \(k = 3\), we have to deal with \(j = 1, 2, \) and \(3\).

**Partials for \(\Delta C_1\) and \(\Delta S_1\).** The sailing partials needed for the first line of equation (4) are obtained by differentiating equations (A6), with \(\phi_3\) and \(\lambda_3\) substituted from equations (A7). With the help of the chain rule, the following results are obtained:

\[
\frac{\partial f_3}{\partial \phi_1} = \frac{\partial f_3}{\partial \phi_3} \frac{\partial f_2}{\partial \phi_1} + \frac{\partial f_3}{\partial \lambda_3} \frac{\partial g_2}{\partial \phi_1}
\]
\[
\frac{\partial f_3}{\partial \lambda_1} = \frac{\partial f_3}{\partial \phi_3} \frac{\partial f_2}{\partial \lambda_1} + \frac{\partial f_3}{\partial \lambda_3} \frac{\partial g_2}{\partial \lambda_1}
\]
\[
\frac{\partial g_3}{\partial \phi_1} = \frac{\partial g_3}{\partial \phi_3} \frac{\partial f_2}{\partial \phi_1} + \frac{\partial g_3}{\partial \lambda_3} \frac{\partial g_2}{\partial \phi_1}
\]
\[
\frac{\partial g_3}{\partial \lambda_1} = \frac{\partial g_3}{\partial \phi_3} \frac{\partial f_2}{\partial \lambda_1} + \frac{\partial g_3}{\partial \lambda_3} \frac{\partial g_2}{\partial \lambda_1}
\]

(A8)

Here, the partials of \(f_3\) and \(g_3\) on the right side are evaluated for the particular time of the observation being processed, from the single-leg formulas applied to leg 3. The partials of \(f_2\) and \(g_2\) are evaluated for time \(t = t_3\) (a requirement of equation (A7)), so we already have their values—they were computed for the artificial observation at the end of leg 2 when equation (A4) was applied.

**Partials for \(\Delta C_1\) and \(\Delta S_1\).** The sailing partials needed for the second line of equation (4) when \(j = 1\) are obtained by the same procedure as used for equations (A8):

\[
\frac{\partial f_3}{\partial C_1} = \frac{\partial f_3}{\partial \phi_3} \frac{\partial f_2}{\partial C_1} + \frac{\partial f_3}{\partial \lambda_3} \frac{\partial g_2}{\partial C_1}
\]
\[
\frac{\partial g_3}{\partial C_1} = \frac{\partial g_3}{\partial \phi_3} \frac{\partial f_2}{\partial C_1} + \frac{\partial g_3}{\partial \lambda_3} \frac{\partial g_2}{\partial C_1}
\]
\[
\frac{\partial f_3}{\partial S_1} = \frac{\partial f_3}{\partial \phi_3} \frac{\partial f_2}{\partial S_1} + \frac{\partial f_3}{\partial \lambda_3} \frac{\partial g_2}{\partial S_1}
\]
\[
\frac{\partial g_3}{\partial S_1} = \frac{\partial g_3}{\partial \phi_3} \frac{\partial f_2}{\partial S_1} + \frac{\partial g_3}{\partial \lambda_3} \frac{\partial g_2}{\partial S_1}
\]

(A9)

The partials of \(f_3\) and \(g_3\) on the right are the same as those in equation (A8). The partials of \(f_2\) and \(g_2\) are evaluated for time \(t = t_3\), the end point of leg 2, and their values were computed when equation (A5) was evaluated for the artificial observation at the end of leg 2.
The pattern should be obvious by now. The partials of the sailing formulas that
φ
the first (earliest) leg. That allows the fix (\(t_{1}\))...
position of the observer’s vessel if desired. In a time-reversed implementation, the observations are taken in reverse chronological order. Each of the artificial observations must then be added at the *beginning* of its leg, so that it is the last computational point encountered on the leg as the observations are processed.
Appendix B

Alternative Multiple-Leg Solution Algorithms

What alternative algorithms are available for the multiple-leg navigational solution? As mentioned in
the main part of the paper, the multiple-leg case is an example of a constrained least-squares problem.
Least-squares theory allows constraint equations—known relationships among the parameters being solved
for—to be included as part of the solution (see, for example, [8], Chapter 9). In principle, this theory would
allow us to use equation (3), with four unknown parameters per leg, in combination with linearized versions
of constraint equations such as (A3) and (A7) in Appendix A. However, this approach is considerably more
difficult computationally, involving, among other things, another matrix inversion. Generally, “canned”
least-squares packages do not provide for this type of solution (although at least one, IMSL [10], does).

Another approach, discussed in [8], uses the constraint equations to eliminate the dependent (redundant)
parameters in the problem. That is, the constraints are used to solve for a set of independent (free) parameters
“up front,” and all the relevant equations are rewritten in terms of this set of independent unknowns. The
algorithm outlined above is actually a variant of this approach. In our case, the coordinates of the starting
points of legs 2 through N are the dependent parameters. The algorithm does not explicitly solve for and
eliminate these parameters—rather, the algorithm works entirely with the derivatives of the parameters, and
uses the chain rule to effectively remove the starting point coordinates of legs 2 through N from the solution.
The solution, therefore, involves only a set of independent parameters.

The direct elimination of the dependent parameters is difficult with the sailing formulas used above but
the method can be illustrated if the vessel’s track is approximated by piecewise polynomials. (Spline theory
is not really applicable, since continuity in derivatives is not required at the junction points.) For short
rhumb lines, latitude can be represented as a linear function of time, although longitude requires a quadratic
polynomial (great circles would require quadratics in both coordinates). Suppose we look at the equations
for longitude for a three-leg problem:

\[
\begin{align*}
\text{Leg 1:} & \quad \lambda(t) = g_1 = \lambda_1 + \dot{\lambda}_1(t - t_1) + \frac{1}{2}\ddot{\lambda}_1(t - t_1)^2 \\
\text{Leg 2:} & \quad \lambda(t) = g_2 = \lambda_2 + \dot{\lambda}_2(t - t_2) + \frac{1}{2}\ddot{\lambda}_2(t - t_2)^2 \\
\text{Leg 3:} & \quad \lambda(t) = g_3 = \lambda_3 + \dot{\lambda}_3(t - t_3) + \frac{1}{2}\ddot{\lambda}_3(t - t_3)^2
\end{align*}
\]

(B1)

These equations contain nine parameters: \(\lambda_1, \dot{\lambda}_1, \ddot{\lambda}_1, \lambda_2, \dot{\lambda}_2, \ddot{\lambda}_2, \lambda_3, \dot{\lambda}_3,\) and \(\ddot{\lambda}_3\). However, two of these, \(\lambda_2\) and \(\lambda_3\), the longitudes at the beginning of legs 2 and 3, are dependent parameters. They can be related to the
other parameters by the usual constraints, which provide for continuity in position at the leg intersections.
For this case, the constraints, analogous to equations (A3) and (A7) in Appendix A, are \(g_2 = g_1\) at \(t = t_2\)
and \(g_3 = g_2\) at \(t = t_3\). These conditions allow us to eliminate \(\lambda_2\) and \(\lambda_3\) from equations (B1), yielding

\[
\begin{align*}
g_1 &= \lambda_1 + \dot{\lambda}_1(t - t_1) + \frac{1}{2}\ddot{\lambda}_1(t - t_1)^2 \\
g_2 &= \lambda_1 + \dot{\lambda}_1(t_2 - t_1) + \frac{1}{2}\ddot{\lambda}_1(t_2 - t_1)^2 + \dot{\lambda}_2(t - t_2) + \frac{1}{2}\ddot{\lambda}_2(t - t_2)^2 \\
g_3 &= \lambda_1 + \dot{\lambda}_1(t_2 - t_1) + \frac{1}{2}\ddot{\lambda}_1(t_2 - t_1)^2 + \dot{\lambda}_2(t_3 - t_2) + \frac{1}{2}\ddot{\lambda}_2(t_3 - t_2)^2 \\
&\quad + \dot{\lambda}_3(t - t_3) + \frac{1}{2}\ddot{\lambda}_3(t - t_3)^2
\end{align*}
\]

(B2)

Equations (B2) are the new sailing formulas for longitude to be used for the three legs, which involve
no dependent parameters. The latitude equations (which have no quadratic terms) can be treated similarly.
We are left with only one geographic point in the problem, defined by the parameters \(\phi_1\) and \(\lambda_1\), plus, for
each leg \(j\), three motion parameters, \(\phi_j\), \(\lambda_j\), and \(\dot{\lambda}_j\). We can then form a conditional equation, similar to
equation (4) in the main text, but with these eleven parameters as unknowns. A least-squares solution would
then be completely straightforward.
This seems to be a simpler approach to the problem, but there are prices to be paid. First, the motion parameters for each leg $j$—that is, $\dot{\phi}_j$, $\lambda_j$, and $\ddot{\lambda}_j$—are somewhat abstract and would have to be transformed to quantities such as course or speed that would be useful to the navigator. Second, there are now three motion parameters to solve for per leg instead of two, requiring more observations for a reliable solution. Third, the polynomial representation of each leg’s track is simply a Taylor expansion of more exact formulas (here, for rhumb lines) and extra terms might be required for long legs, depending on the accuracy requirements. Every extra term adds another free parameter to the problem, and the requirement for more observations. The algorithm presented in the main text of this paper and Appendix A is thus more economical in its use of the available observations, a critical consideration.
